

Package ‘bioregion’

July 22, 2025

Type Package

Title Comparison of Bioregionalisation Methods

Version 1.2.0

Description The main purpose of this package is to propose a transparent methodological framework to compare bioregionalisation methods based on hierarchical and non-hierarchical clustering algorithms (Kreft & Jetz (2010) <[doi:10.1111/j.1365-2699.2010.02375.x](https://doi.org/10.1111/j.1365-2699.2010.02375.x)>) and network algorithms (Lenormand et al. (2019) <[doi:10.1002/ece3.4718](https://doi.org/10.1002/ece3.4718)> and Leroy et al. (2019) <[doi:10.1111/jbi.13674](https://doi.org/10.1111/jbi.13674)>).

betapart_to_bioregion *Convert betapart dissimilarity to bioregion dissimilarity*

Description

This function converts dissimilarity results produced by the betapart package (and packages using betapart, such as phyloregion) into a dissimilarity object compatible with the bioregion package. This function only converts object types to make them compatible with bioregion; it does not modify the beta-diversity values. This function allows the inclusion of phylogenetic beta diversity to compute bioregions with bioregion.

Usage

```
betapart_to_bioregion(betapart_result)
```

Arguments

betapart_result

An object produced by the betapart package (e.g., using the beta.pair function).

Value

A dissimilarity object of class bioregion.pairwise.metric, compatible with the bioregion package.

Author(s)

Boris Leroy (<leroy.boris@gmail.com>)
Maxime Lenormand (<maxime.lenormand@inrae.fr>)
Pierre Denelle (<pierre.denelle@gmail.com>)

Examples

```
comat <- matrix(sample(0:1000, size = 50, replace = TRUE,  
  prob = 1 / 1:1001), 5, 10)  
rownames(comat) <- paste0("Site", 1:5)  
colnames(comat) <- paste0("Species", 1:10)  
  
## Not run:  
beta_div <- betapart::beta.pair.abund(comat)  
betapart_to_bioregion(beta_div)  
  
## End(Not run)
```

bioregionalization_metrics

Calculate metrics for one or several bioregionalizations

Description

This function calculates metrics for one or several bioregionalizations, typically based on outputs from `netclu_`, `hclu_`, or `nhclu_` functions. Some metrics may require users to provide either a similarity or dissimilarity matrix, or the initial species-site table.

Usage

```
bioregionalization_metrics(
  bioregionalization,
  dissimilarity = NULL,
  dissimilarity_index = NULL,
  net = NULL,
  site_col = 1,
  species_col = 2,
  eval_metric = "all"
)
```

Arguments

<code>bioregionalization</code>	A <code>bioregion.clusters</code> object.
<code>dissimilarity</code>	A <code>dist</code> object or a <code>bioregion.pairwise.metric</code> object (output from similarity_to_dissimilarity()). Required if <code>eval_metric</code> includes "pc_distance" and <code>tree</code> is not a <code>bioregion.hierar.tree</code> object.
<code>dissimilarity_index</code>	A character string indicating the dissimilarity (beta-diversity) index to use if <code>dissimilarity</code> is a <code>data.frame</code> with multiple dissimilarity indices.
<code>net</code>	The site-species network (i.e., bipartite network). Should be provided as a <code>data.frame</code> if <code>eval_metric</code> includes "avg_endemism" or "tot_endemism".
<code>site_col</code>	The name or index of the column representing site nodes (i.e., primary nodes). Should be provided if <code>eval_metric</code> includes "avg_endemism" or "tot_endemism".
<code>species_col</code>	The name or index of the column representing species nodes (i.e., feature nodes). Should be provided if <code>eval_metric</code> includes "avg_endemism" or "tot_endemism".
<code>eval_metric</code>	A character vector or a single character string indicating the metric(s) to be calculated to assess the effect of different numbers of clusters. Available options are "pc_distance", "anosim", "avg_endemism", or "tot_endemism". If "all" is specified, all metrics will be calculated.

Details

Evaluation metrics:

- `pc_distance`: This metric, as used by Holt et al. (2013), is the ratio of the between-cluster sum of dissimilarities (beta-diversity) to the total sum of dissimilarities for the full dissimilarity matrix. It is calculated in two steps:
 - Compute the total sum of dissimilarities by summing all elements of the dissimilarity matrix.
 - Compute the between-cluster sum of dissimilarities by setting within-cluster dissimilarities to zero and summing the matrix. The `pc_distance` ratio is obtained by dividing the between-cluster sum of dissimilarities by the total sum of dissimilarities.
- `anosim`: This metric is the statistic used in the Analysis of Similarities, as described in Castro-Insua et al. (2018). It compares between-cluster and within-cluster dissimilarities. The statistic is computed as: $R = (r_B - r_W) / (N(N-1) / 4)$, where r_B and r_W are the average ranks of between-cluster and within-cluster dissimilarities, respectively, and N is the total number of sites. Note: This function does not estimate significance; for significance testing, use `vegan::anosim()`.
- `avg_endemism`: This metric is the average percentage of endemism in clusters, as recommended by Kreft & Jetz (2010). It is calculated as: $End_mean = \sum_i (E_i / S_i) / K$, where E_i is the number of endemic species in cluster i , S_i is the number of species in cluster i , and K is the total number of clusters.
- `tot_endemism`: This metric is the total endemism across all clusters, as recommended by Kreft & Jetz (2010). It is calculated as: $End_tot = E / C$, where E is the total number of endemic species (i.e., species found in only one cluster) and C is the number of non-endemic species.

Value

A list of class `bioregion.bioregionalization.metrics` with two to three elements:

- `args`: Input arguments.
- `evaluation_df`: A `data.frame` containing the `eval_metric` values for all explored numbers of clusters.
- `endemism_results`: If endemism calculations are requested, a list with the endemism results for each bioregionalization.

a
```

bioregion_metrics

Calculate contribution metrics for bioregions

Description

This function calculates the number of sites per bioregion, as well as the number of species these sites have, the number of endemic species, and the proportion of endemism.

Usage

```
bioregion_metrics(bioregionalization, comat, map = NULL, col_bioregion = NULL)
```

Arguments

bioregionalization A `bioregion.clusters` object.

comat A co-occurrence matrix with sites as rows and species as columns.

map A spatial `sf` data.frame with sites and bioregions. It is the output of the function `map_bioregions`. `NULL` by default.

col_bioregion An integer specifying the column position of the bioregion.

Details

Endemic species are species found only in the sites belonging to one bioregion.

Value

A data.frame with 5 columns, or 6 if spatial coherence is computed.

                  comat = comat)
```

 compare_bioregionalizations

Compare cluster memberships among multiple bioregionalizations

Description

This function computes pairwise comparisons for several bioregionalizations, usually outputs from `netclu_`, `hclu_`, or `nhclu_` functions. It also provides the confusion matrix from pairwise comparisons, enabling the user to compute additional comparison metrics.

Usage

```
compare_bioregionalizations(
  bioregionalizations,
  indices = c("rand", "jaccard"),
  cor_frequency = FALSE,
  store_pairwise_membership = TRUE,
  store_confusion_matrix = TRUE
)
```

Arguments

<code>bioregionalizations</code>	A <code>data.frame</code> object where each row corresponds to a site, and each column to a bioregionalization.
<code>indices</code>	NULL or character. Indices to compute for the pairwise comparison of bioregionalizations. Currently available metrics are "rand" and "jaccard".
<code>cor_frequency</code>	A boolean. If TRUE, computes the correlation between each bioregionalization and the total frequency of co-membership of items across all bioregionalizations. This is useful for identifying which bioregionalization(s) is(are) most representative of all computed bioregionalizations.
<code>store_pairwise_membership</code>	A boolean. If TRUE, stores the pairwise membership of items in the output object.
<code>store_confusion_matrix</code>	A boolean. If TRUE, stores the confusion matrices of pairwise bioregionalization comparisons in the output object.

Details

This function operates in two main steps:

1. Within each bioregionalization, the function compares all pairs of items and documents whether they are clustered together (TRUE) or separately (FALSE). For example, if site 1 and site 2 are clustered in the same cluster in bioregionalization 1, their pairwise membership `site1_site2` will be TRUE. This output is stored in the `pairwise_membership` slot if `store_pairwise_membership = TRUE`.

2. Across all bioregionalizations, the function compares their pairwise memberships to determine similarity. For each pair of bioregionalizations, it computes a confusion matrix with the following elements:

- a: Number of item pairs grouped in both bioregionalizations.
- b: Number of item pairs grouped in the first but not in the second bioregionalization.
- c: Number of item pairs grouped in the second but not in the first bioregionalization.
- d: Number of item pairs not grouped in either bioregionalization.

The confusion matrix is stored in `confusion_matrix` if `store_confusion_matrix = TRUE`.

Based on these confusion matrices, various indices can be computed to measure agreement among bioregionalizations. The currently implemented indices are:

- **Rand index:** $(a + d) / (a + b + c + d)$ Measures agreement by considering both grouped and ungrouped item pairs.
- **Jaccard index:** $a / (a + b + c)$ Measures agreement based only on grouped item pairs.

These indices are complementary: the Jaccard index evaluates clustering similarity, while the Rand index considers both clustering and separation. For example, if two bioregionalizations never group the same pairs, their Jaccard index will be 0, but their Rand index may be > 0 due to ungrouped pairs.

Users can compute additional indices manually using the list of confusion matrices.

To identify which bioregionalization is most representative of the others, the function can compute the correlation between the pairwise membership of each bioregionalization and the total frequency of pairwise membership across all bioregionalizations. This is enabled by setting `cor_frequency = TRUE`.

Value

A list containing 4 to 7 elements:

1. **args:** A list of user-provided arguments.
2. **inputs:** A list containing information on the input bioregionalizations, such as the number of items clustered.
3. **pairwise_membership** (optional): If `store_pairwise_membership = TRUE`, a boolean matrix where TRUE indicates two items are in the same cluster, and FALSE indicates they are not.
4. **freq_item_pw_membership:** A numeric vector containing the number of times each item pair is clustered together, corresponding to the sum of rows in `pairwise_membership`.
5. **bioregionalization_freq_cor** (optional): If `cor_frequency = TRUE`, a numeric vector of correlations between individual bioregionalizations and the total frequency of pairwise membership.
6. **confusion_matrix** (optional): If `store_confusion_matrix = TRUE`, a list of confusion matrices for each pair of bioregionalizations.
7. **bioregionalization_comparison:** A data.frame containing comparison results, where the first column indicates the bioregionalizations compared, and the remaining columns contain the requested indices.

compare_df <- merge(compare_df, bioregion3$clusters, by = "ID")
colnames(compare_df) <- c("Site", "Hclu", "Greedy", "Walktrap")
rownames(compare_df) <- compare_df$Site
compare_df <- compare_df[, c("Hclu", "Greedy", "Walktrap")]

# Running the function
compare_bioregionalizations(compare_df)

# Find out which bioregionalizations are most representative
compare_bioregionalizations(compare_df,
  cor_frequency = TRUE)
```

cut_tree

Cut a hierarchical tree

Description

This function is designed to work on a hierarchical tree and cut it at user-selected heights. It works with outputs from either `hclu_hierarclust` or `hclust` objects. The function allows for cutting the tree based on the chosen number(s) of clusters or specified height(s). Additionally, it includes a procedure to automatically determine the cutting height for the requested number(s) of clusters.

Usage

```
cut_tree(
  tree,
  n_clust = NULL,
  cut_height = NULL,
  find_h = TRUE,
  h_max = 1,
  h_min = 0,
  dynamic_tree_cut = FALSE,
  dynamic_method = "tree",
  dynamic_minClusterSize = 5,
  dissimilarity = NULL,
  ...
)
```

Arguments

tree	A <code>bioregion.hierar.tree</code> or an <code>hclust</code> object.
n_clust	An integer vector or a single integer indicating the number of clusters to be obtained from the hierarchical tree, or the output from bioregionalization_metrics() . This should not be used concurrently with <code>cut_height</code> .
cut_height	A numeric vector specifying the height(s) at which the tree should be cut. This should not be used concurrently with <code>n_clust</code> or <code>optim_method</code> .
find_h	A boolean indicating whether the cutting height should be determined for the requested <code>n_clust</code> .
h_max	A numeric value indicating the maximum possible tree height for determining the cutting height when <code>find_h = TRUE</code> .
h_min	A numeric value specifying the minimum possible height in the tree for determining the cutting height when <code>find_h = TRUE</code> .
dynamic_tree_cut	A boolean indicating whether the dynamic tree cut method should be used. If <code>TRUE</code> , <code>n_clust</code> and <code>cut_height</code> are ignored.
dynamic_method	A character string specifying the method to be used for dynamically cutting the tree: either <code>"tree"</code> (clusters searched only within the tree) or <code>"hybrid"</code> (clusters searched in both the tree and the dissimilarity matrix).
dynamic_minClusterSize	An integer indicating the minimum cluster size for the dynamic tree cut method (see dynamicTreeCut::cutreeDynamic()).
dissimilarity	Relevant only if <code>dynamic_method = "hybrid"</code> . Provide the dissimilarity data.frame used to build the tree.
...	Additional arguments passed to dynamicTreeCut::cutreeDynamic() to customize the dynamic tree cut method.

Details

The function supports two main methods for cutting the tree. First, the tree can be cut at a uniform height (specified by `cut_height` or determined automatically for the requested `n_clust`). Second, the dynamic tree cut method (Langfelder et al., 2008) can be applied, which adapts to the shape of branches in the tree, cutting at varying heights based on cluster positions.

The dynamic tree cut method has two variants:

- The tree-based variant (`dynamic_method = "tree"`) uses a top-down approach, relying solely on the tree and the order of clustered objects.
- The hybrid variant (`dynamic_method = "hybrid"`) employs a bottom-up approach, leveraging both the tree and the dissimilarity matrix to identify clusters based on dissimilarity among sites. This approach is useful for detecting outliers within clusters.

Value

If `tree` is an output from `hclu_hierarclust()`, the same object is returned with updated content (i.e., `args` and `clusters`). If `tree` is an `hclust` object, a `data.frame` containing the clusters is returned.

Note

The `find_h` argument is ignored if `dynamic_tree_cut = TRUE`, as cutting heights cannot be determined in this case.

clusters_2 <- cut_tree(hclust_tree, n_clust = 10)

cluster_dynamic <- cut_tree(tree1, dynamic_tree_cut = TRUE,
                          dissimilarity = dissimilarity)

```

dissimilarity	<i>Compute dissimilarity metrics (beta-diversity) between sites based on species composition</i>
---------------	--

Description

This function generates a data.frame where each row provides one or several dissimilarity metrics between pairs of sites, based on a co-occurrence matrix with sites as rows and species as columns.

Usage

```
dissimilarity(comat, metric = "Simpson", formula = NULL, method = "prodmat")
```

Arguments

comat	A co-occurrence matrix with sites as rows and species as columns.
metric	A character vector or a single character string specifying the metrics to compute (see Details). Available options are "abc", "ABC", "Jaccard", "Jaccardturn", "Sorensen", "Simpson", "Bray", "Brayturn", and "Euclidean". If "all" is specified, all metrics will be calculated. Can be set to NULL if formula is used.
formula	A character vector or a single character string specifying custom formula(s) based on the a, b, c, A, B, and C quantities (see Details). The default is NULL.
method	A character string specifying the method to compute abc (see Details). The default is "prodmat", which is more efficient but memory-intensive. Alternatively, "loops" is less memory-intensive but slower.

Details

With a the number of species shared by a pair of sites, b species only present in the first site and c species only present in the second site.

$$\text{Jaccard} = (b + c) / (a + b + c)$$

$$\text{Jaccardturn} = 2\min(b, c) / (a + 2\min(b, c)) \text{ (Baselga, 2012)}$$

$$\text{Sorensen} = (b + c) / (2a + b + c)$$

$$\text{Simpson} = \min(b, c) / (a + \min(b, c))$$

If abundances data are available, Bray-Curtis and its turnover component can also be computed with the following equation:

$$\text{Bray} = (B + C) / (2A + B + C)$$

$$\text{Brayturn} = \min(B, C) / (A + \min(B, C)) \text{ (Baselga, 2013)}$$

with A the sum of the lesser values for common species shared by a pair of sites. B and C are the total number of specimens counted at both sites minus A .

formula can be used to compute customized metrics with the terms a , b , c , A , B , and C . For example `formula = c("pmin(b,c) / (a + pmin(b,c))", "(B + C) / (2*A + B + C)")` will compute the Simpson and Bray-Curtis dissimilarity metrics, respectively. Note that `pmin` is used in the Simpson formula because a , b , c , A , B and C are numeric vectors.

Euclidean computes the Euclidean distance between each pair of sites.

Value

A `data.frame` with the additional class `bioregion.pairwise.metric`, containing one or several dissimilarity metrics between pairs of sites. The first two columns represent the pairs of sites. There is one column per similarity metric provided in `metric` and `formula`, except for the `abc` and `ABC` metrics, which are stored in three separate columns (one for each letter).

dissim <- dissimilarity(comat, metric = "all",
  formula = "1 - (b + c) / (a + b + c)")
```

dissimilarity_to_similarity

Convert dissimilarity metrics to similarity metrics

Description

This function converts a data.frame of dissimilarity metrics (beta diversity) between sites into similarity metrics.

Usage

```
dissimilarity_to_similarity(dissimilarity, include_formula = TRUE)
```

Arguments

dissimilarity the output object from `dissimilarity()` or `similarity_to_dissimilarity()`.
include_formula a boolean indicating whether metrics based on custom formula(s) should also be converted (see Details). The default is TRUE.

Value

A data.frame with the additional class `bioregion.pairwise.metric`, providing similarity metrics for each pair of sites based on a dissimilarity object.

Note

The behavior of this function changes depending on column names. Columns `Site1` and `Site2` are copied identically. If there are columns called `a`, `b`, `c`, `A`, `B`, `C` they will also be copied identically. If there are columns based on your own formula (argument `formula` in `dissimilarity()`) or not in the original list of dissimilarity metrics (argument `metrics` in `dissimilarity()`) and if the argument `include_formula` is set to FALSE, they will also be copied identically. Otherwise there are going to be converted like they other columns (default behavior).

If a column is called `Euclidean`, the similarity will be calculated based on the following formula:

Euclidean similarity = $1 / (1 - \text{Euclidean distance})$

Otherwise, all other columns will be transformed into dissimilarity with the following formula:

similarity = $1 - \text{dissimilarity}$

find_optimal_n	<i>Search for an optimal number of clusters in a list of bioregionalizations</i>
----------------	--

Description

This function aims to optimize one or several criteria on a set of ordered bioregionalizations. It is typically used to find one or more optimal cluster counts on hierarchical trees to cut or ranges of bioregionalizations from k-means or PAM. Users should exercise caution in other cases (e.g., unordered bioregionalizations or unrelated bioregionalizations).

Usage

```
find_optimal_n(
  bioregionalizations,
  metrics_to_use = "all",
  criterion = "elbow",
  step_quantile = 0.99,
```

```

    step_levels = NULL,
    step_round_above = TRUE,
    metric_cutoffs = c(0.5, 0.75, 0.9, 0.95, 0.99, 0.999),
    n_breakpoints = 1,
    plot = TRUE
  )

```

Arguments

bioregionalizations	A <code>bioregion.bioregionalization.metrics</code> object (output from <code>bioregionalization_metrics()</code>) or a <code>data.frame</code> with the first two columns named K (bioregionalization name) and n_clusters (number of clusters), followed by columns with numeric evaluation metrics.
metrics_to_use	A character vector or single string specifying metrics in bioregionalizations for calculating optimal clusters. Defaults to "all" (uses all metrics).
criterion	A character string specifying the criterion to identify optimal clusters. Options include "elbow", "increasing_step", "decreasing_step", "cutoff", "breakpoints", "min", or "max". Defaults to "elbow". See Details.
step_quantile	For "increasing_step" or "decreasing_step", specifies the quantile of differences between consecutive bioregionalizations as the cutoff to identify significant steps in eval_metric.
step_levels	For "increasing_step" or "decreasing_step", specifies the number of largest steps to retain as cutoffs.
step_round_above	A boolean indicating whether the optimal clusters are above (TRUE) or below (FALSE) identified steps. Defaults to TRUE.
metric_cutoffs	For criterion = "cutoff", specifies the cutoffs of eval_metric to extract cluster counts.
n_breakpoints	Specifies the number of breakpoints to find in the curve. Defaults to 1.
plot	A boolean indicating if a plot of the first eval_metric with identified optimal clusters should be drawn.

Details

This function explores evaluation metric ~ cluster relationships, applying criteria to find optimal cluster counts.

Note on criteria: Several criteria can return multiple optimal cluster counts, emphasizing hierarchical or nested bioregionalizations. This approach aligns with modern recommendations for biological datasets, as seen in Ficaretola et al. (2017)'s reanalysis of Holt et al. (2013).

Criteria for optimal clusters:

- **elbow:** Identifies the "elbow" point in the evaluation metric curve, where incremental improvements diminish. Based on a method to find the maximum distance from a straight line linking curve endpoints.

- `increasing_step` or `decreasing_step`: Highlights significant increases or decreases in metrics by analyzing pairwise differences between bioregionalizations. Users specify `step_quantile` or `step_levels`.
- `cutoffs`: Derives clusters from specified metric cutoffs, e.g., as in Holt et al. (2013). Adjust cutoffs based on spatial scale.
- `breakpoints`: Uses segmented regression to find breakpoints. Requires specifying `n_breakpoints`.
- `min` & `max`: Selects clusters at minimum or maximum metric values.

Value

A list of class `bioregion.optimal.n` with these elements:

- `args`: Input arguments.
- `evaluation_df`: The input evaluation data frame, appended with boolean columns for optimal cluster counts.
- `optimal_nb_clusters`: A list with optimal cluster counts for each metric in `"metrics_to_use"`, based on the chosen criterion.
- `plot`: The plot (if requested).

Note

Please note that finding the optimal number of clusters is a procedure which normally requires decisions from the users, and as such can hardly be fully automatized. Users are strongly advised to read the references indicated below to look for guidance on how to choose their optimal number(s) of clusters. Consider the "optimal" numbers of clusters returned by this function as first approximation of the best numbers for your bioregionalization.

fishdf

*Spatial distribution of fish in Europe (data.frame)***Description**

A dataset containing the abundance of 195 species in 338 sites.

Usage

```
fishdf
```

Format

A data.frame with 2,703 rows and 3 columns:

Site Unique site identifier (corresponding to the field ID of fishsf)

Species Unique species identifier

Abundance Species abundance

fishmat	<i>Spatial distribution of fish in Europe (co-occurrence matrix)</i>
---------	--

Description

A dataset containing the abundance of each of the 195 species in each of the 338 sites.

Usage

fishmat

Format

A co-occurrence matrix with sites as rows and species as columns. Each element of the matrix represents the abundance of the species in the site.

fishsf	<i>Spatial distribution of fish in Europe</i>
--------	---

Description

A dataset containing the geometry of the 338 sites.

Usage

fishsf

Format

A

ID Unique site identifier

geometry Geometry of the site

hclu_diana	<i>Divisive hierarchical clustering based on dissimilarity or beta-diversity</i>
------------	--

Description

This function computes a divisive hierarchical clustering from a dissimilarity (beta-diversity) `data.frame`, calculates the cophenetic correlation coefficient, and can generate clusters from the tree if requested by the user. The function implements randomization of the dissimilarity matrix to generate the tree, with a selection method based on the optimal cophenetic correlation coefficient. Typically, the dissimilarity `data.frame` is a `bioregion.pairwise.metric` object obtained by running `similarity` or `similarity` followed by `similarity_to_dissimilarity`.

Usage

```
hclu_diana(
  dissimilarity,
  index = names(dissimilarity)[3],
  n_clust = NULL,
  cut_height = NULL,
  find_h = TRUE,
  h_max = 1,
  h_min = 0
)
```

Arguments

<code>dissimilarity</code>	The output object from <code>dissimilarity()</code> or <code>similarity_to_dissimilarity()</code> , or a <code>dist</code> object. If a <code>data.frame</code> is used, the first two columns represent pairs of sites (or any pair of nodes), and the remaining column(s) contain the dissimilarity indices.
<code>index</code>	The name or number of the dissimilarity column to use. By default, the third column name of <code>dissimilarity</code> is used.
<code>n_clust</code>	An integer vector or a single integer indicating the number of clusters to be obtained from the hierarchical tree, or the output from <code>bioregionalization_metrics</code> . Should not be used concurrently with <code>cut_height</code> .
<code>cut_height</code>	A numeric vector indicating the height(s) at which the tree should be cut. Should not be used concurrently with <code>n_clust</code> .
<code>find_h</code>	A boolean indicating whether the cutting height should be determined for the requested <code>n_clust</code> .
<code>h_max</code>	A numeric value indicating the maximum possible tree height for the chosen index.
<code>h_min</code>	A numeric value indicating the minimum possible height in the tree for the chosen index.

Details

The function is based on [diana](#). Chapter 6 of Kaufman & Rousseeuw (1990) fully details the functioning of the diana algorithm.

To find an optimal number of clusters, see [bioregionalization_metrics\(\)](#)

Value

A list of class `bioregion.clusters` with five slots:

1. **name**: A character string containing the name of the algorithm.
2. **args**: A list of input arguments as provided by the user.
3. **inputs**: A list describing the characteristics of the clustering process.
4. **algorithm**: A list containing all objects associated with the clustering procedure, such as the original cluster objects.
5. **clusters**: A `data.frame` containing the clustering results.

hclu_hierarclust	<i>Hierarchical clustering based on dissimilarity or beta-diversity</i>
------------------	---

Description

This function generates a hierarchical tree from a dissimilarity (beta-diversity) `data.frame`, calculates the cophenetic correlation coefficient, and optionally retrieves clusters from the tree upon user request. The function includes a randomization process for the dissimilarity matrix to generate the tree, with two methods available for constructing the final tree. Typically, the dissimilarity `data.frame` is a `bioregion.pairwise.metric` object obtained by running `similarity`, or by running `similarity` followed by `similarity_to_dissimilarity`.

Usage

```
hclu_hierarclust(
  dissimilarity,
  index = names(dissimilarity)[3],
  method = "average",
  randomize = TRUE,
  n_runs = 100,
  keep_trials = FALSE,
  optimal_tree_method = "iterative_consensus_tree",
  n_clust = NULL,
  cut_height = NULL,
  find_h = TRUE,
  h_max = 1,
  h_min = 0,
  consensus_p = 0.5,
  verbose = TRUE
)
```

Arguments

dissimilarity	The output object from <code>dissimilarity()</code> or <code>similarity_to_dissimilarity()</code> , or a <code>dist</code> object. If a <code>data.frame</code> is used, the first two columns represent pairs of sites (or any pair of nodes), and the subsequent column(s) contain the dissimilarity indices.
index	The name or number of the dissimilarity column to use. By default, the third column name of <code>dissimilarity</code> is used.
method	The name of the hierarchical classification method, as in <code>hclust</code> . Should be one of "ward.D", "ward.D2", "single", "complete", "average" (= UPGMA), "mcquitty" (= WPGMA), "median" (= WPGMC), or "centroid" (= UPGMC).
randomize	A boolean indicating whether the dissimilarity matrix should be randomized to account for the order of sites in the dissimilarity matrix.
n_runs	The number of trials for randomizing the dissimilarity matrix.

keep_trials	A boolean indicating whether all random trial results should be stored in the output object. Set to FALSE to save space if your dissimilarity object is large. Note that this cannot be set to TRUE if optimal_tree_method = "iterative_consensus_tree".
optimal_tree_method	A character string indicating how the final tree should be obtained from all trials. Possible values are "iterative_consensus_tree" (default), "best", and "consensus". We recommend "iterative_consensus_tree". See Details.
n_clust	An integer vector or a single integer indicating the number of clusters to be obtained from the hierarchical tree, or the output from bioregionalization_metrics . This parameter should not be used simultaneously with cut_height.
cut_height	A numeric vector indicating the height(s) at which the tree should be cut. This parameter should not be used simultaneously with n_clust.
find_h	A boolean indicating whether the height of the cut should be found for the requested n_clust.
h_max	A numeric value indicating the maximum possible tree height for the chosen index.
h_min	A numeric value indicating the minimum possible height in the tree for the chosen index.
consensus_p	A numeric value (applicable only if optimal_tree_method = "consensus") indicating the threshold proportion of trees that must support a region/cluster for it to be included in the final consensus tree.
verbose	A boolean (applicable only if optimal_tree_method = "iterative_consensus_tree") indicating whether to display progress messages. Set to FALSE to suppress these messages.

Details

The function is based on [hclust](#). The default method for the hierarchical tree is average, i.e. UPGMA as it has been recommended as the best method to generate a tree from beta diversity dissimilarity (Kreft & Jetz, 2010).

Clusters can be obtained by two methods:

- Specifying a desired number of clusters in `n_clust`
- Specifying one or several heights of cut in `cut_height`

To find an optimal number of clusters, see [bioregionalization_metrics\(\)](#)

It is important to pay attention to the fact that the order of rows in the input distance matrix influences the tree topology as explained in Dapporto (2013). To address this, the function generates multiple trees by randomizing the distance matrix.

Two methods are available to obtain the final tree:

- `optimal_tree_method = "iterative_consensus_tree"`: The Iterative Hierarchical Consensus Tree (IHCT) method reconstructs a consensus tree by iteratively splitting the dataset into two subclusters based on the pairwise dissimilarity of sites across `n_runs` trees based on `n_runs` randomizations of the distance matrix. At each iteration, it identifies the majority membership of sites into two stable groups across all trees, calculates the height based on

the selected linkage method (method), and enforces monotonic constraints on node heights to produce a coherent tree structure. This approach provides a robust, hierarchical representation of site relationships, balancing cluster stability and hierarchical constraints.

- `optimal_tree_method = "best"`: This method selects one tree among with the highest cophenetic correlation coefficient, representing the best fit between the hierarchical structure and the original distance matrix.
- `optimal_tree_method = "consensus"`: This method constructs a consensus tree using phylogenetic methods with the function `consensus`. When using this option, you must set the `consensus_p` parameter, which indicates the proportion of trees that must contain a region/cluster for it to be included in the final consensus tree. Consensus trees lack an inherent height because they represent a majority structure rather than an actual hierarchical clustering. To assign heights, we use a non-negative least squares method (`nnls.tree`) based on the initial distance matrix, ensuring that the consensus tree preserves approximate distances among clusters.

We recommend using the `"iterative_consensus_tree"` as all the branches of this tree will always reflect the majority decision among many randomized versions of the distance matrix. This method is inspired by Dapporto et al. (2015), which also used the majority decision among many randomized versions of the distance matrix, but it expands it to reconstruct the entire topology of the tree iteratively.

We do not recommend using the basic consensus method because in many contexts it provides inconsistent results, with a meaningless tree topology and a very low cophenetic correlation coefficient.

For a fast exploration of the tree, we recommend using the best method which will only select the tree with the highest cophenetic correlation coefficient among all randomized versions of the distance matrix.

Value

A list of class `bioregion.clusters` with five slots:

1. **name**: A character string containing the name of the algorithm.
2. **args**: A list of input arguments as provided by the user.
3. **inputs**: A list describing the characteristics of the clustering process.
4. **algorithm**: A list containing all objects associated with the clustering procedure, such as the original cluster objects.
5. **clusters**: A `data.frame` containing the clustering results.

In the `algorithm` slot, users can find the following elements:

- `trials`: A list containing all randomization trials. Each trial includes the dissimilarity matrix with randomized site order, the associated tree, and the cophenetic correlation coefficient (Spearman) for that tree.
- `final.tree`: An `hclust` object representing the final hierarchical tree to be used.
- `final.tree.coph.cor`: The cophenetic correlation coefficient between the initial dissimilarity matrix and the `final.tree`.

hclu_optics

OPTICS hierarchical clustering algorithm

Description

This function performs semi-hierarchical clustering based on dissimilarity using the OPTICS algorithm (Ordering Points To Identify the Clustering Structure).

Usage

```
hclu_optics(
  dissimilarity,
  index = names(dissimilarity)[3],
  minPts = NULL,
  eps = NULL,
  xi = 0.05,
  minimum = FALSE,
  show_hierarchy = FALSE,
  algorithm_in_output = TRUE,
  ...
)
```

Arguments

- | | |
|---------------|--|
| dissimilarity | The output object from dissimilarity() or similarity_to_dissimilarity() , or a dist object. If a data.frame is used, the first two columns represent pairs of sites (or any pair of nodes), and the subsequent column(s) contain the dissimilarity indices. |
| index | The name or number of the dissimilarity column to use. By default, the third column name of dissimilarity is used. |
| minPts | A numeric value specifying the minPts argument of dbscan . minPts is the minimum number of points required to form a dense region. By default, it is set to the natural logarithm of the number of sites in dissimilarity. |
| eps | A numeric value specifying the eps argument of optics . It defines the upper limit of the size of the epsilon neighborhood. Limiting the neighborhood size improves performance and has no or very little impact on the ordering as long as it is not set too low. If not specified (default behavior), the largest minPts-distance in the dataset is used, which gives the same result as infinity. |
| xi | A numeric value specifying the steepness threshold to identify clusters hierarchically using the Xi method (see optics). |

minimum	A boolean specifying whether the hierarchy should be pruned from the output to only retain clusters at the "minimal" level, i.e., only leaf / non-overlapping clusters. If TRUE, then the argument show_hierarchy should be set to FALSE.
show_hierarchy	A boolean specifying whether the hierarchy of clusters should be included in the output. By default, the hierarchy is not visible in the clusters obtained from OPTICS; it can only be visualized by plotting the OPTICS object. If show_hierarchy = TRUE, the output cluster data.frame will contain additional columns showing the hierarchy of clusters.
algorithm_in_output	A boolean indicating whether the original output of dbscan should be returned in the output (TRUE by default, see Value).
...	Additional arguments to be passed to <code>optics()</code> (see optics).

Details

The OPTICS (Ordering points to identify the clustering structure) is a semi-hierarchical clustering algorithm which orders the points in the dataset such that points which are closest become neighbors, and calculates a reachability distance for each point. Then, clusters can be extracted in a hierarchical manner from this reachability distance, by identifying clusters depending on changes in the relative cluster density. The reachability plot should be explored to understand the clusters and their hierarchical nature, by running `plot` on the output of the function if `algorithm_in_output = TRUE`: `plot(object$algorithm)`. We recommend reading (Hahsler et al., 2019) to grasp the algorithm, how it works, and what the clusters mean.

To extract the clusters, we use the [extractXi](#) function which is based on the steepness of the reachability plot (see [optics](#))

Value

A list of class `bioregion.clusters` with five slots:

1. **name**: A character string containing the name of the algorithm.
2. **args**: A list of input arguments as provided by the user.
3. **inputs**: A list describing the characteristics of the clustering process.
4. **algorithm**: A list containing all objects associated with the clustering procedure, such as the original cluster objects.
5. **clusters**: A data.frame containing the clustering results.

In the `algorithm` slot, if `algorithm_in_output = TRUE`, users can find the output of [optics](#).

clust1
```

install_binaries	<i>Download, unzip, check permissions, and test the bioregion's binary files</i>
------------------	--

Description

This function downloads and unzips the 'bin' folder required to run certain functions of the bioregion package. It also verifies if the files have the necessary permissions to be executed as programs. Finally, it tests whether the binary files are running correctly.

Usage

```
install_binaries(
  binpath = "tempdir",
  download_only = FALSE,
  infomap_version = c("2.1.0", "2.6.0", "2.7.1", "2.8.0")
)
```

Arguments

binpath	A character string specifying the path to the folder that will host the bin folder containing the binary files (see Details).
download_only	A logical value indicating whether the function should only download the bin.zip file or perform the entire process (see Details).
infomap_version	A character vector or a single character string specifying the Infomap version(s) to install.

Details

By default, the binary files are installed in R's temporary directory (`binpath = "tempdir"`). In this case, the bin folder will be automatically removed at the end of the R session. Alternatively, the binary files can be installed in the bioregion package folder (`binpath = "pkgfolder"`).

A custom folder path can also be specified. In this case, and only in this case, `download_only` can be set to `TRUE`, but you must ensure that the files have the required permissions to be executed as programs.

In all cases, PLEASE MAKE SURE to update the `binpath` and `check_install` parameters accordingly in `netclu_infomap`, `netclu_louvain`, and `netclu_oslom`.

Value

No return value.

Note

Currently, only Infomap versions 2.1.0, 2.6.0, 2.7.1, and 2.8.0 are available.

map_bioregions

Create a map of bioregions

Description

This plot function can be used to visualize bioregions based on a `bioregion.clusters` object combined with a geometry (sf objects).

Usage

```
map_bioregions(clusters, geometry, write_clusters = FALSE, plot = TRUE, ...)
```

Arguments

clusters	An object of class <code>bioregion.clusters</code> or a <code>data.frame</code> . If a <code>data.frame</code> is used, the first column should represent the sites' ID, and the subsequent column(s) should represent the clusters.
geometry	A spatial object that can be handled by the <code>sf</code> package. The first attribute should correspond to the sites' ID (see Details).
write_clusters	A boolean indicating if the clusters should be added to the geometry.
plot	A boolean indicating if the plot should be drawn.
...	Further arguments to be passed to <code>sf::plot()</code> .

Details

The clusters and geometry site IDs should correspond. They should have the same type (i.e., character if clusters is a `bioregion.clusters` object) and the sites of clusters should be included in the sites of geometry.

Value

One or several maps of bioregions if `plot = TRUE` and the geometry with additional clusters' attributes if `write_clusters = TRUE`.

Author(s)

Maxime Lenormand (<maxime.lenormand@inrae.fr>
 Boris Leroy (<leroy.boris@gmail.com>
 Pierre Denelle (<pierre.denelle@gmail.com>)

Examples

```
data(fishmat)
data(fishsf)

net <- similarity(fishmat, metric = "Simpson")
clu <- netclu_greedy(net)
map <- map_bioregions(clu, fishsf, write_clusters = TRUE, plot = FALSE)
```

mat_to_net

Create a data.frame from a contingency table

Description

This function generates a two- or three-column `data.frame`, where each row represents the interaction between two nodes (e.g., site and species) and an optional third column indicates the weight of the interaction (if `weight = TRUE`). The input is a contingency table, with rows representing one set of entities (e.g., site) and columns representing another set (e.g., species).

Usage

```
mat_to_net(  
  mat,  
  weight = FALSE,  
  remove_zeroes = TRUE,  
  include_diag = TRUE,  
  include_lower = TRUE  
)
```

Arguments

mat	A contingency table (i.e., a matrix).
weight	A logical value indicating whether the values in the matrix should be interpreted as interaction weights.
remove_zeroes	A logical value determining whether interactions with a weight equal to 0 should be excluded from the output.
include_diag	A logical value indicating whether the diagonal (self-interactions) should be included in the output. This applies only to square matrices.
include_lower	A logical value indicating whether the lower triangular part of the matrix should be included in the output. This applies only to square matrices.

Value

A data.frame where each row represents the interaction between two nodes. If weight = TRUE, the data.frame includes a third column representing the weight of each interaction.

Associated functions: [net_to_mat](#)

Examples

```
mat <- matrix(sample(1000, 50), 5, 10)  
rownames(mat) <- paste0("Site", 1:5)  
colnames(mat) <- paste0("Species", 1:10)  
  
net <- mat_to_net(mat, weight = TRUE)
```

netclu_beckett	<i>Community structure detection in weighted bipartite networks via modularity optimization</i>
----------------	---

Description

This function takes a bipartite weighted graph and computes modules by applying Newman's modularity measure in a bipartite weighted version.

Usage

```
netclu_beckett(
  net,
  weight = TRUE,
  cut_weight = 0,
  index = names(net)[3],
  seed = NULL,
  forceLPA = FALSE,
  site_col = 1,
  species_col = 2,
  return_node_type = "both",
  algorithm_in_output = TRUE
)
```

Arguments

net	A data.frame representing a bipartite network with the first two columns representing undirected links between pairs of nodes, and the next column(s) representing the weights of the links.
weight	A boolean indicating whether weights should be considered if there are more than two columns (see Note).
cut_weight	A minimal weight value. If weight is TRUE, links with weights strictly lower than this value will not be considered (0 by default).
index	The name or number of the column to use as weight. By default, the third column name of net is used.
seed	The seed for the random number generator (NULL for random by default).
forceLPA	A boolean indicating whether the even faster pure LPA-algorithm of Beckett should be used. DIRT-LPA (the default) is less likely to get trapped in a local minimum but is slightly slower. Defaults to FALSE.
site_col	The name or number of the column for site nodes (i.e., primary nodes).
species_col	The name or number of the column for species nodes (i.e., feature nodes).
return_node_type	A character indicating which types of nodes ("site", "species", or "both") should be returned in the output ("both" by default).

algorithm_in_output

A boolean indicating whether the original output of `computeModules` should be returned in the output (TRUE by default, see Value).

Details

This function is based on the modularity optimization algorithm provided by Stephen Beckett (Beckett, 2016) as implemented in the `bipartite` package (`computeModules`).

Value

A list of class `bioregion.clusters` with five slots:

1. **name**: A character containing the name of the algorithm.
2. **args**: A list of input arguments as provided by the user.
3. **inputs**: A list of characteristics of the clustering process.
4. **algorithm**: A list of all objects associated with the clustering procedure, such as original cluster objects (only if `algorithm_in_output = TRUE`).
5. **clusters**: A `data.frame` containing the clustering results.

If `algorithm_in_output = TRUE`, users can find the output of `computeModules` in the `algorithm` slot.

Note

Beckett's algorithm is designed to handle weighted bipartite networks. If `weight = FALSE`, a weight of 1 will be assigned to each pair of nodes. Ensure that the `site_col` and `species_col` arguments correctly identify the respective columns for site nodes (primary nodes) and species nodes (feature nodes). The type of nodes returned in the output can be selected using the `return_node_type` argument: "both" to include both node types, "site" to return only site nodes, or "species" to return only species nodes.

Associated functions: `netclu_infomap` `netclu_louvain` `netclu_oslom`

Examples

```
net <- data.frame(
  Site = c(rep("A", 2), rep("B", 3), rep("C", 2)),
  Species = c("a", "b", "a", "c", "d", "b", "d"),
  Weight = c(10, 100, 1, 20, 50, 10, 20))

com <- netclu_beckett(net)
```

netclu_greedy

Community structure detection via greedy optimization of modularity

Description

This function finds communities in a (un)weighted undirected network via greedy optimization of modularity.

Usage

```
netclu_greedy(
  net,
  weight = TRUE,
  cut_weight = 0,
  index = names(net)[3],
  bipartite = FALSE,
  site_col = 1,
  species_col = 2,
  return_node_type = "both",
  algorithm_in_output = TRUE
)
```

Arguments

net	The output object from similarity() or dissimilarity_to_similarity() . If a <code>data.frame</code> is used, the first two columns represent pairs of sites (or any pair of nodes), and the next column(s) are the similarity indices.
weight	A boolean indicating if the weights should be considered if there are more than two columns.
cut_weight	A minimal weight value. If <code>weight</code> is <code>TRUE</code> , the links between sites with a weight strictly lower than this value will not be considered (0 by default).
index	The name or number of the column to use as weight. By default, the third column name of <code>net</code> is used.
bipartite	A boolean indicating if the network is bipartite (see Details).
site_col	The name or number for the column of site nodes (i.e. primary nodes).
species_col	The name or number for the column of species nodes (i.e. feature nodes).

return_node_type

A character indicating what types of nodes (site, species or both) should be returned in the output (return_node_type = "both" by default).

algorithm_in_output

A boolean indicating if the original output of [cluster_fast_greedy](#) should be returned in the output (TRUE by default, see Value).

Details

This function is based on the fast greedy modularity optimization algorithm (Clauset et al., 2004) as implemented in the [igraph](#) package ([cluster_fast_greedy](#)).

Value

A list of class `bioregion.clusters` with five slots:

1. **name**: character containing the name of the algorithm
2. **args**: list of input arguments as provided by the user
3. **inputs**: list of characteristics of the clustering process
4. **algorithm**: list of all objects associated with the clustering procedure, such as original cluster objects (only if `algorithm_in_output = TRUE`)
5. **clusters**: `data.frame` containing the clustering results

In the `algorithm` slot, if `algorithm_in_output = TRUE`, users can find the output of [cluster_fast_greedy](#).

Note

Although this algorithm was not primarily designed to deal with bipartite network, it is possible to consider the bipartite network as unipartite network (`bipartite = TRUE`).

Do not forget to indicate which of the first two columns is dedicated to the site nodes (i.e. primary nodes) and species nodes (i.e. feature nodes) using the arguments `site_col` and `species_col`. The type of nodes returned in the output can be chosen with the argument `return_node_type` equal to `both` to keep both types of nodes, `sites` to preserve only the sites nodes and `species` to preserve only the species nodes.

netclu_infomap	<i>Infomap community finding</i>
----------------	----------------------------------

Description

This function finds communities in a (un)weighted (un)directed network based on the Infomap algorithm (<https://github.com/mapequation/infomap>).

Usage

```
netclu_infomap(
  net,
  weight = TRUE,
  cut_weight = 0,
  index = names(net)[3],
  seed = NULL,
  nbmod = 0,
  markovtime = 1,
  numtrials = 1,
  twolevel = FALSE,
  show_hierarchy = FALSE,
  directed = FALSE,
  bipartite_version = FALSE,
  bipartite = FALSE,
  site_col = 1,
  species_col = 2,
  return_node_type = "both",
  version = "2.8.0",
  binpath = "tempdir",
```

```

    check_install = TRUE,
    path_temp = "infomap_temp",
    delete_temp = TRUE
)

```

Arguments

net	The output object from similarity() or dissimilarity_to_similarity() . If a <code>data.frame</code> is used, the first two columns represent pairs of sites (or any pair of nodes), and the next column(s) are the similarity indices.
weight	A boolean indicating if the weights should be considered if there are more than two columns.
cut_weight	A minimal weight value. If weight is TRUE, the links between sites with a weight strictly lower than this value will not be considered (0 by default).
index	The name or number of the column to use as weight. By default, the third column name of net is used.
seed	The seed for the random number generator (NULL for random by default).
nbmod	Penalize solutions the more they differ from this number (0 by default for no preferred number of modules).
markovtime	Scales link flow to change the cost of moving between modules, higher values result in fewer modules (1 by default).
numtrials	For the number of trials before picking up the best solution.
twolevel	A boolean indicating if the algorithm should optimize a two-level partition of the network (FALSE by default for multi-level).
show_hierarchy	A boolean specifying if the hierarchy of community should be identifiable in the outputs (FALSE by default).
directed	A boolean indicating if the network is directed (from column 1 to column 2).
bipartite_version	A boolean indicating if the bipartite version of Infomap should be used (see Note).
bipartite	A boolean indicating if the network is bipartite (see Note).
site_col	The name or number for the column of site nodes (i.e. primary nodes).
species_col	The name or number for the column of species nodes (i.e. feature nodes).
return_node_type	A character indicating what types of nodes ("site", "species", or "both") should be returned in the output ("both" by default).
version	A character indicating the Infomap version to use.
binpath	A character indicating the path to the bin folder (see install_binaries and Details).
check_install	A boolean indicating if the function should check that the Infomap has been properly installed (see install_binaries and Details).
path_temp	A character indicating the path to the temporary folder (see Details).
delete_temp	A boolean indicating if the temporary folder should be removed (see Details).

Details

Infomap is a network clustering algorithm based on the Map equation proposed in Rosvall & Bergstrom (2008) that finds communities in (un)weighted and (un)directed networks.

This function is based on the C++ version of Infomap (<https://github.com/mapequation/infomap/releases>). This function needs binary files to run. They can be installed with `install_binaries`.

If you changed the default path to the bin folder while running `install_binaries` PLEASE MAKE SURE to set `binpath` accordingly.

If you did not use `install_binaries` to change the permissions and test the binary files PLEASE MAKE SURE to set `check_install` accordingly.

The C++ version of Infomap generates temporary folders and/or files that are stored in the `path_temp` folder ("infomap_temp" with a unique timestamp located in the bin folder in `binpath` by default). This temporary folder is removed by default (`delete_temp` = TRUE).

Several versions of Infomap are available in the package. See `install_binaries` for more details.

Value

A list of class `bioregion.clusters` with five slots:

1. **name**: A character containing the name of the algorithm.
2. **args**: A list of input arguments as provided by the user.
3. **inputs**: A list of characteristics of the clustering process.
4. **algorithm**: A list of all objects associated with the clustering procedure, such as original cluster objects.
5. **clusters**: A `data.frame` containing the clustering results.

In the `algorithm` slot, users can find the following elements:

- `cmd`: The command line used to run Infomap.
- `version`: The Infomap version.
- `web`: Infomap's GitHub repository.

Note

Infomap has been designed to deal with bipartite networks. To use this functionality, set the `bipartite_version` argument to TRUE in order to approximate a two-step random walker (see <https://www.mapequation.org/infomap/> for more information). Note that a bipartite network can also be considered as a unipartite network (`bipartite` = TRUE).

In both cases, do not forget to indicate which of the first two columns is dedicated to the site nodes (i.e., primary nodes) and species nodes (i.e. feature nodes) using the arguments `site_col` and `species_col`. The type of nodes returned in the output can be chosen with the argument `return_node_type` equal to "both" to keep both types of nodes, "site" to preserve only the site nodes, and "species" to preserve only the species nodes.

netclu_labelprop

Finding communities based on propagating labels

Description

This function finds communities in a (un)weighted undirected network based on propagating labels.

Usage

```
netclu_labelprop(
  net,
  weight = TRUE,
  cut_weight = 0,
  index = names(net)[3],
  seed = NULL,
  bipartite = FALSE,
  site_col = 1,
  species_col = 2,
  return_node_type = "both",
  algorithm_in_output = TRUE
)
```

Arguments

net	The output object from similarity() or dissimilarity_to_similarity() . If a data.frame is used, the first two columns represent pairs of sites (or any pair of nodes), and the next column(s) are the similarity indices.
weight	A boolean indicating if the weights should be considered if there are more than two columns.
cut_weight	A minimal weight value. If weight is TRUE, the links between sites with a weight strictly lower than this value will not be considered (0 by default).
index	The name or number of the column to use as weight. By default, the third column name of net is used.
seed	The seed for the random number generator (NULL for random by default).
bipartite	A boolean indicating if the network is bipartite (see Details).
site_col	The name or number for the column of site nodes (i.e. primary nodes).
species_col	The name or number for the column of species nodes (i.e. feature nodes).
return_node_type	A character indicating what types of nodes ("site", "species", or "both") should be returned in the output ("both" by default).
algorithm_in_output	A boolean indicating if the original output of cluster_label_prop should be returned in the output (TRUE by default, see Value).

Details

This function is based on propagating labels (Raghavan et al., 2007) as implemented in the [igraph](#) package ([cluster_label_prop](#)).

Value

A list of class `bioregion.clusters` with five slots:

1. **name:** A character containing the name of the algorithm.
2. **args:** A list of input arguments as provided by the user.
3. **inputs:** A list of characteristics of the clustering process.
4. **algorithm:** A list of all objects associated with the clustering procedure, such as original cluster objects (only if `algorithm_in_output = TRUE`).
5. **clusters:** A data.frame containing the clustering results.

In the algorithm slot, if `algorithm_in_output = TRUE`, users can find a "communities" object, output of [cluster_label_prop](#).

Note

Although this algorithm was not primarily designed to deal with bipartite networks, it is possible to consider the bipartite network as a unipartite network (`bipartite = TRUE`).

Do not forget to indicate which of the first two columns is dedicated to the site nodes (i.e., primary nodes) and species nodes (i.e. feature nodes) using the arguments `site_col` and `species_col`. The

type of nodes returned in the output can be chosen with the argument `return_node_type` equal to "both" to keep both types of nodes, "site" to preserve only the site nodes, and "species" to preserve only the species nodes.

netclu_leadingeigen	<i>Finding communities based on the leading eigenvector of the community matrix</i>
---------------------	---

Description

This function finds communities in a (un)weighted undirected network based on the leading eigenvector of the community matrix.

Usage

```
netclu_leadingeigen(
  net,
  weight = TRUE,
  cut_weight = 0,
```

```

    index = names(net)[3],
    bipartite = FALSE,
    site_col = 1,
    species_col = 2,
    return_node_type = "both",
    algorithm_in_output = TRUE
  )

```

Arguments

net	The output object from similarity() or dissimilarity_to_similarity() . If a data.frame is used, the first two columns represent pairs of sites (or any pair of nodes), and the next column(s) are the similarity indices.
weight	A boolean indicating if the weights should be considered if there are more than two columns.
cut_weight	A minimal weight value. If weight is TRUE, the links between sites with a weight strictly lower than this value will not be considered (0 by default).
index	The name or number of the column to use as weight. By default, the third column name of net is used.
bipartite	A boolean indicating if the network is bipartite (see Details).
site_col	The name or number for the column of site nodes (i.e., primary nodes).
species_col	The name or number for the column of species nodes (i.e., feature nodes).
return_node_type	A character indicating what types of nodes ("site", "species", or "both") should be returned in the output ("both" by default).
algorithm_in_output	A boolean indicating if the original output of cluster_leading_eigen should be returned in the output (TRUE by default, see Value).

Details

This function is based on the leading eigenvector of the community matrix (Newman, 2006) as implemented in the [igraph](#) package ([cluster_leading_eigen](#)).

Value

A list of class `bioregion.clusters` with five slots:

1. **name:** A character containing the name of the algorithm.
2. **args:** A list of input arguments as provided by the user.
3. **inputs:** A list of characteristics of the clustering process.
4. **algorithm:** A list of all objects associated with the clustering procedure, such as original cluster objects (only if `algorithm_in_output = TRUE`).
5. **clusters:** A data.frame containing the clustering results.

In the `algorithm` slot, if `algorithm_in_output = TRUE`, users can find the output of [cluster_leading_eigen](#).

Note

Although this algorithm was not primarily designed to deal with bipartite networks, it is possible to consider the bipartite network as a unipartite network (`bipartite = TRUE`).

Do not forget to indicate which of the first two columns is dedicated to the site nodes (i.e., primary nodes) and species nodes (i.e. feature nodes) using the arguments `site_col` and `species_col`. The type of nodes returned in the output can be chosen with the argument `return_node_type` equal to "both" to keep both types of nodes, "site" to preserve only the site nodes, and "species" to preserve only the species nodes.

clust2 <- netclu_leadingeigen(net_bip, bipartite = TRUE)
```

Description

This function finds communities in a (un)weighted undirected network based on the Leiden algorithm of Traag, van Eck & Waltman.

Usage

```
netclu_leiden(
  net,
  weight = TRUE,
  cut_weight = 0,
  index = names(net)[3],
  seed = NULL,
  objective_function = "CPM",
  resolution_parameter = 1,
  beta = 0.01,
  n_iterations = 2,
  vertex_weights = NULL,
  bipartite = FALSE,
  site_col = 1,
  species_col = 2,
  return_node_type = "both",
  algorithm_in_output = TRUE
)
```

Arguments

net	The output object from similarity() or dissimilarity_to_similarity() . If a data.frame is used, the first two columns represent pairs of sites (or any pair of nodes), and the next column(s) are the similarity indices.
weight	A boolean indicating if the weights should be considered if there are more than two columns.
cut_weight	A minimal weight value. If weight is TRUE, the links between sites with a weight strictly lower than this value will not be considered (0 by default).
index	The name or number of the column to use as weight. By default, the third column name of net is used.
seed	The random number generator seed (NULL for random by default).
objective_function	A string indicating the objective function to use, either the Constant Potts Model ("CPM") or "modularity" ("CPM" by default).
resolution_parameter	The resolution parameter to use. Higher resolutions lead to smaller communities, while lower resolutions lead to larger communities.
beta	A parameter affecting the randomness in the Leiden algorithm. This affects only the refinement step of the algorithm.
n_iterations	The number of iterations for the Leiden algorithm. Each iteration may further improve the partition.
vertex_weights	The vertex weights used in the Leiden algorithm. If not provided, they will be automatically determined based on the objective_function. Please see the details of this function to understand how to interpret the vertex weights.
bipartite	A boolean indicating if the network is bipartite (see Details).

site_col	The name or number for the column of site nodes (i.e., primary nodes).
species_col	The name or number for the column of species nodes (i.e., feature nodes).
return_node_type	A character indicating what types of nodes ("site", "species", or "both") should be returned in the output ("both" by default).
algorithm_in_output	A boolean indicating if the original output of cluster_leiden should be returned in the output (TRUE by default, see Value).

Details

This function is based on the Leiden algorithm (Traag et al., 2019) as implemented in the [igraph](#) package ([cluster_leiden](#)).

Value

A list of class `bioregion.clusters` with five slots:

1. **name:** A character containing the name of the algorithm.
2. **args:** A list of input arguments as provided by the user.
3. **inputs:** A list of characteristics of the clustering process.
4. **algorithm:** A list of all objects associated with the clustering procedure, such as original cluster objects (only if `algorithm_in_output = TRUE`).
5. **clusters:** A `data.frame` containing the clustering results.

In the `algorithm` slot, if `algorithm_in_output = TRUE`, users can find the output of [cluster_leiden](#).

Note

Although this algorithm was not primarily designed to deal with bipartite networks, it is possible to consider the bipartite network as a unipartite network (`bipartite = TRUE`).

Do not forget to indicate which of the first two columns is dedicated to the site nodes (i.e., primary nodes) and species nodes (i.e. feature nodes) using the arguments `site_col` and `species_col`. The type of nodes returned in the output can be chosen with the argument `return_node_type` equal to "both" to keep both types of nodes, "site" to preserve only the site nodes, and "species" to preserve only the species nodes.

```

Arguments

net	The output object from similarity() or dissimilarity_to_similarity() . If a <code>data.frame</code> is used, the first two columns represent pairs of sites (or any pair of nodes), and the next column(s) are the similarity indices.
weight	A boolean indicating if the weights should be considered if there are more than two columns.
cut_weight	A minimal weight value. If weight is TRUE, the links between sites with a weight strictly lower than this value will not be considered (0 by default).
index	The name or number of the column to use as weight. By default, the third column name of net is used.
lang	A string indicating which version of Louvain should be used ("igraph" or "cpp", see Details).
resolution	A resolution parameter to adjust the modularity (1 is chosen by default, see Details).
seed	The random number generator seed (only when lang = "igraph", NULL for random by default).
q	The quality function used to compute the partition of the graph (modularity is chosen by default, see Details).
c	The parameter for the Owsinski-Zadrozny quality function (between 0 and 1, 0.5 is chosen by default).
k	The kappa_min value for the Shi-Malik quality function (it must be > 0, 1 is chosen by default).
bipartite	A boolean indicating if the network is bipartite (see Details).
site_col	The name or number for the column of site nodes (i.e., primary nodes).
species_col	The name or number for the column of species nodes (i.e., feature nodes).
return_node_type	A character indicating what types of nodes ("site", "species", or "both") should be returned in the output ("both" by default).
binpath	A character indicating the path to the bin folder (see install_binaries and Details).
check_install	A boolean indicating if the function should check that Louvain has been properly installed (see install_binaries and Details).
path_temp	A character indicating the path to the temporary folder (see Details).
delete_temp	A boolean indicating if the temporary folder should be removed (see Details).
algorithm_in_output	A boolean indicating if the original output of cluster_louvain should be returned in the output (TRUE by default, see Value).

Details

Louvain is a network community detection algorithm proposed in (Blondel et al., 2008). This function offers two implementations of the Louvain algorithm (controlled by the `lang` parameter): the **igraph** implementation (`cluster_louvain`) and the C++ implementation (<https://sourceforge.net/projects/louvain/>, version 0.3).

The **igraph** implementation allows adjustment of the resolution parameter of the modularity function (resolution argument) used internally by the algorithm. Lower values typically yield fewer, larger clusters. The original definition of modularity is recovered when the resolution parameter is set to 1 (by default).

The C++ implementation provides several quality functions: $q = 0$ for the classical Newman-Girvan criterion (Modularity), $q = 1$ for the Zahn-Condorcet criterion, $q = 2$ for the Owsinski-Zadrozny criterion (parameterized by c), $q = 3$ for the Goldberg Density criterion, $q = 4$ for the A-weighted Condorcet criterion, $q = 5$ for the Deviation to Indetermination criterion, $q = 6$ for the Deviation to Uniformity criterion, $q = 7$ for the Profile Difference criterion, $q = 8$ for the Shi-Malik criterion (parameterized by k), and $q = 9$ for the Balanced Modularity criterion.

The C++ version is based on version 0.3 (<https://sourceforge.net/projects/louvain/>). Binary files are required to run it, and can be installed with `install_binaries`.

If you changed the default path to the bin folder while running `install_binaries`, PLEASE MAKE SURE to set `binpath` accordingly.

If you did not use `install_binaries` to change the permissions or test the binary files, PLEASE MAKE SURE to set `check_install` accordingly.

The C++ version generates temporary folders and/or files in the `path_temp` folder ("louvain_temp" with a unique timestamp located in the bin folder in `binpath` by default). This temporary folder is removed by default (`delete_temp = TRUE`).

Value

A list of class `bioregion.clusters` with five slots:

1. **name**: A character containing the name of the algorithm.
2. **args**: A list of input arguments as provided by the user.
3. **inputs**: A list of characteristics of the clustering process.
4. **algorithm**: A list of all objects associated with the clustering procedure, such as original cluster objects (only if `algorithm_in_output = TRUE`).
5. **clusters**: A data.frame containing the clustering results.

In the `algorithm` slot, if `algorithm_in_output = TRUE`, users can find the output of `cluster_louvain` if `lang = "igraph"` and the following element if `lang = "cpp"`:

- `cmd`: The command line used to run Louvain.
- `version`: The Louvain version.
- `web`: The Louvain's website.

Note

Although this algorithm was not primarily designed to deal with bipartite networks, it is possible to consider the bipartite network as a unipartite network (`bipartite = TRUE`).

Do not forget to indicate which of the first two columns is dedicated to the site nodes (i.e., primary nodes) and species nodes (i.e., feature nodes) using the arguments `site_col` and `species_col`. The type of nodes returned in the output can be chosen with the argument `return_node_type` equal to "both" to keep both types of nodes, "site" to preserve only the site nodes, and "species" to preserve only the species nodes.

net <- similarity(comat, metric = "Simpson")
com <- netclu_louvain(net, lang = "igraph")
```

 netclu_oslom

OSLOM community finding

Description

This function finds communities in a (un)weighted (un)directed network based on the OSLOM algorithm (<http://oslom.org/>, version 2.4).

Usage

```
netclu_oslom(
  net,
  weight = TRUE,
  cut_weight = 0,
  index = names(net)[3],
  seed = NULL,
  reassign = "no",
  r = 10,
  hr = 50,
  t = 0.1,
  cp = 0.5,
  directed = FALSE,
  bipartite = FALSE,
  site_col = 1,
  species_col = 2,
  return_node_type = "both",
  binpath = "tempdir",
  check_install = TRUE,
  path_temp = "oslom_temp",
  delete_temp = TRUE
)
```

Arguments

net	The output object from similarity() or dissimilarity_to_similarity() . If a data.frame is used, the first two columns represent pairs of sites (or any pair of nodes), and the next column(s) are the similarity indices.
weight	A boolean indicating if the weights should be considered if there are more than two columns.
cut_weight	A minimal weight value. If weight is TRUE, the links between sites with a weight strictly lower than this value will not be considered (0 by default).
index	Name or number of the column to use as weight. By default, the third column name of net is used.
seed	For the random number generator (NULL for random by default).
reassign	A character indicating if the nodes belonging to several community should be reassigned and what method should be used (see Note).
r	The number of runs for the first hierarchical level (10 by default).
hr	The number of runs for the higher hierarchical level (50 by default, 0 if you are not interested in hierarchies).
t	The p-value, the default value is 0.10. Increase this value if you want more modules.
cp	Kind of resolution parameter used to decide between taking some modules or their union (default value is 0.5; a bigger value leads to bigger clusters).
directed	A boolean indicating if the network is directed (from column 1 to column 2).

bipartite	A boolean indicating if the network is bipartite (see Details).
site_col	Name or number for the column of site nodes (i.e. primary nodes).
species_col	Name or number for the column of species nodes (i.e. feature nodes).
return_node_type	A character indicating what types of nodes (site, species, or both) should be returned in the output (return_node_type = "both" by default).
binpath	A character indicating the path to the bin folder (see install_binaries and Details).
check_install	A boolean indicating if the function should check that the OSLOM has been properly installed (see install_binaries and Details).
path_temp	A character indicating the path to the temporary folder (see Details).
delete_temp	A boolean indicating if the temporary folder should be removed (see Details).

Details

OSLOM is a network community detection algorithm proposed in Lancichinetti et al. (2011) that finds statistically significant (overlapping) communities in (un)weighted and (un)directed networks. This function is based on the 2.4 C++ version of OSLOM (<http://www.oslom.org/software.htm>). This function needs files to run. They can be installed with [install_binaries](#).

If you changed the default path to the bin folder while running [install_binaries](#), PLEASE MAKE SURE to set binpath accordingly.

If you did not use [install_binaries](#) to change the permissions and test the binary files, PLEASE MAKE SURE to set check_install accordingly.

The C++ version of OSLOM generates temporary folders and/or files that are stored in the path_temp folder (folder "oslom_temp" with a unique timestamp located in the bin folder in binpath by default). This temporary folder is removed by default (delete_temp = TRUE).

Value

A list of class `bioregion.clusters` with five slots:

1. **name:** A character containing the name of the algorithm.
2. **args:** A list of input arguments as provided by the user.
3. **inputs:** A list of characteristics of the clustering process.
4. **algorithm:** A list of all objects associated with the clustering procedure, such as original cluster objects (only if `algorithm_in_output = TRUE`).
5. **clusters:** A data.frame containing the clustering results.

In the `algorithm` slot, users can find the following elements:

- `cmd`: The command line used to run OSLOM.
- `version`: The OSLOM version.
- `web`: The OSLOM's web site.

Note

Although this algorithm was not primarily designed to deal with bipartite networks, it is possible to consider the bipartite network as unipartite network (`bipartite = TRUE`). Do not forget to indicate which of the first two columns is dedicated to the site nodes (i.e. primary nodes) and species nodes (i.e. feature nodes) using the arguments `site_col` and `species_col`. The type of nodes returned in the output can be chosen with the argument `return_node_type` equal to both to keep both types of nodes, sites to preserve only the sites nodes, and species to preserve only the species nodes.

Since OSLOM potentially returns overlapping communities, we propose two methods to reassign the 'overlapping' nodes: randomly (`reassign = "random"`) or based on the closest candidate community (`reassign = "simil"`) (only for weighted networks, in this case the closest candidate community is determined with the average similarity). By default, `reassign = "no"` and all the information will be provided. The number of partitions will depend on the number of overlapping modules (up to three). The suffix `_semel`, `_bis`, and `_ter` are added to the column names. The first partition (`_semel`) assigns a module to each node. A value of NA in the second (`_bis`) and third (`_ter`) columns indicates that no overlapping module was found for this node (i.e. non-overlapping nodes).

netclu_walktrap

Community structure detection via short random walks

Description

This function finds communities in a (un)weighted undirected network via short random walks.

Usage

```
netclu_walktrap(
  net,
  weight = TRUE,
  cut_weight = 0,
  index = names(net)[3],
  steps = 4,
  bipartite = FALSE,
  site_col = 1,
  species_col = 2,
  return_node_type = "both",
  algorithm_in_output = TRUE
)
```

Arguments

net	The output object from similarity() or dissimilarity_to_similarity() . If a data.frame is used, the first two columns represent pairs of sites (or any pair of nodes), and the next column(s) are the similarity indices.
weight	A boolean indicating if the weights should be considered if there are more than two columns.
cut_weight	A minimal weight value. If weight is TRUE, the links between sites with a weight strictly lower than this value will not be considered (0 by default).
index	Name or number of the column to use as weight. By default, the third column name of net is used.
steps	The length of the random walks to perform.
bipartite	A boolean indicating if the network is bipartite (see Details).
site_col	Name or number for the column of site nodes (i.e. primary nodes).
species_col	Name or number for the column of species nodes (i.e. feature nodes).
return_node_type	A character indicating what types of nodes (site, species, or both) should be returned in the output (return_node_type = "both" by default).
algorithm_in_output	A boolean indicating if the original output of cluster_walktrap should be returned in the output (TRUE by default, see Value).

Details

This function is based on random walks (Pons & Latapy, 2005) as implemented in the [igraph](#) package ([cluster_walktrap](#)).

Value

A list of class `bioregion.clusters` with five slots:

1. **name**: A character containing the name of the algorithm.
2. **args**: A list of input arguments as provided by the user.
3. **inputs**: A list of characteristics of the clustering process.
4. **algorithm**: A list of all objects associated with the clustering procedure, such as original cluster objects (only if `algorithm_in_output = TRUE`).
5. **clusters**: A data.frame containing the clustering results.

In the `algorithm` slot, if `algorithm_in_output = TRUE`, users can find the output of [cluster_walktrap](#).

Note

Although this algorithm was not primarily designed to deal with bipartite networks, it is possible to consider the bipartite network as unipartite network (`bipartite = TRUE`).

Do not forget to indicate which of the first two columns is dedicated to the site nodes (i.e. primary nodes) and species nodes (i.e. feature nodes) using the arguments `site_col` and `species_col`. The type of nodes returned in the output can be chosen with the argument `return_node_type` equal to both to keep both types of nodes, `sites` to preserve only the site nodes, and `species` to preserve only the species nodes.

clust2 <- netclu_walktrap(net_bip, bipartite = TRUE)
```

net_to_mat	<i>Create a contingency table from a data.frame</i>
------------	---

Description

This function generates a contingency table from a two- or three-column data.frame, where each row represents the interaction between two nodes (e.g., site and species) and an optional third column indicates the weight of the interaction (if weight = TRUE).

Usage

```
net_to_mat(
  net,
  weight = FALSE,
  squared = FALSE,
  symmetrical = FALSE,
  missing_value = 0
)
```

Arguments

net	A two- or three-column data.frame where each row represents the interaction between two nodes (e.g., site and species), with an optional third column indicating the weight of the interaction.
weight	A logical value indicating whether the weight column should be considered.
squared	A logical value indicating whether the output matrix should be square (i.e., containing the same nodes in rows and columns).
symmetrical	A logical value indicating whether the resulting matrix should be symmetrical. This applies only if squared = TRUE. Note that different weights associated with opposite pairs already present in net will be preserved.
missing_value	The value to assign to pairs of nodes not present in net. Defaults to 0.

Value

A matrix with the first nodes (from the first column of net) as rows and the second nodes (from the second column of net) as columns. If squared = TRUE, the rows and columns will have the same number of elements, corresponding to the unique union of objects in the first and second columns of net. If squared = TRUE and symmetrical = TRUE, the matrix will be forced to be symmetrical based on the upper triangular part of the matrix.

  Weight = c(10, 100, 1, 20, 50, 10, 20)
)

mat <- net_to_mat(net, weight = TRUE)
```

 nhclu_affprop

Non-hierarchical clustering: Affinity Propagation

Description

This function performs non-hierarchical clustering using the Affinity Propagation algorithm.

Usage

```
nhclu_affprop(
  similarity,
  index = names(similarity)[3],
  seed = NULL,
  p = NA,
  q = NA,
  maxits = 1000,
  convits = 100,
```

```

    lam = 0.9,
    details = FALSE,
    nonoise = FALSE,
    K = NULL,
    prc = NULL,
    bimaxit = NULL,
    exact = NULL,
    algorithm_in_output = TRUE
  )

```

Arguments

similarity	The output object from similarity() or dissimilarity_to_similarity() , or a <code>dist</code> object. If a <code>data.frame</code> is used, the first two columns should represent pairs of sites (or any pair of nodes), and the subsequent column(s) should contain the similarity indices.
index	The name or number of the similarity column to use. By default, the third column name of <code>similarity</code> is used.
seed	The seed for the random number generator used when <code>nonoise = FALSE</code> .
p	Input preference, which can be a vector specifying individual preferences for each data point. If scalar, the same value is used for all data points. If <code>NA</code> , exemplar preferences are initialized based on the distribution of non-Inf values in the similarity matrix, controlled by <code>q</code> .
q	If <code>p = NA</code> , exemplar preferences are initialized according to the distribution of non-Inf values in the similarity matrix. By default, the median is used. A value between 0 and 1 specifies the sample quantile, where <code>q = 0.5</code> results in the median.
maxits	The maximum number of iterations to execute.
convits	The algorithm terminates if the exemplars do not change for <code>convits</code> iterations.
lam	The damping factor, a value in the range <code>[0.5, 1)</code> . Higher values correspond to heavier damping, which may help prevent oscillations.
details	If <code>TRUE</code> , detailed information about the algorithm's progress is stored in the output object.
nonoise	If <code>TRUE</code> , disables the addition of a small amount of noise to the similarity object, which prevents degenerate cases.
K	The desired number of clusters. If not <code>NULL</code> , the function apclusterK is called.
prc	A parameter needed when <code>K</code> is not <code>NULL</code> . The algorithm stops if the number of clusters deviates by less than <code>prc</code> percent from the desired value <code>K</code> . Set to 0 to enforce exactly <code>K</code> clusters.
bimaxit	A parameter needed when <code>K</code> is not <code>NULL</code> . Specifies the maximum number of bisection steps to perform. No warning is issued if the number of clusters remains outside the desired range.
exact	A flag indicating whether to compute the initial preference range exactly.
algorithm_in_output	A boolean indicating whether to include the original output of apcluster in the result. Defaults to <code>TRUE</code> .

Details

This function is based on the **apcluster** package ([apcluster](#)).

Value

A list of class `bioregion.clusters` with five slots:

1. **name**: A character string containing the name of the algorithm.
2. **args**: A list of input arguments as provided by the user.
3. **inputs**: A list describing the characteristics of the clustering process.
4. **algorithm**: A list of objects associated with the clustering procedure, such as original cluster objects (if `algorithm_in_output = TRUE`).
5. **clusters**: A data.frame containing the clustering results.

If `algorithm_in_output = TRUE`, the `algorithm` slot includes the output of [apcluster](#).

```

nhclu_clara

Non-hierarchical clustering: CLARA

Description

This function performs non-hierarchical clustering based on dissimilarity using partitioning around medoids, implemented via the Clustering Large Applications (CLARA) algorithm.

Usage

```

nhclu_clara(
  dissimilarity,
  index = names(dissimilarity)[3],
  seed = NULL,
  n_clust = c(1, 2, 3),
  maxiter = 0,
  initializer = "LAB",
  fasttol = 1,
  numsamples = 5,
  sampling = 0.25,
  independent = FALSE,
  algorithm_in_output = TRUE
)

```

Arguments

dissimilarity The output object from [dissimilarity\(\)](#) or [similarity_to_dissimilarity\(\)](#), or a dist object. If a data.frame is used, the first two columns should represent pairs of sites (or any pair of nodes), and the subsequent column(s) should contain the dissimilarity indices.

index	The name or number of the dissimilarity column to use. By default, the third column name of dissimilarity is used.
seed	A value for the random number generator (set to NULL for random initialization by default).
n_clust	An integer vector or a single integer specifying the desired number(s) of clusters.
maxiter	An integer defining the maximum number of iterations.
initializer	A character string, either "BUILD" (used in the classic PAM algorithm) or "LAB" (Linear Approximate BUILD).
fasttol	A positive numeric value defining the tolerance for fast swapping behavior. Defaults to 1.
numsamples	A positive integer specifying the number of samples to draw.
sampling	A positive numeric value defining the sampling rate.
independent	A boolean indicating whether the previous medoids are excluded in the next sample. Defaults to FALSE.
algorithm_in_output	A boolean indicating whether the original output of fastclara should be included in the output. Defaults to TRUE (see Value).

Details

Based on [fastkmedoids](#) package ([fastclara](#)).

Value

A list of class `bioregion.clusters` with five components:

1. **name**: A character string containing the name of the algorithm.
2. **args**: A list of input arguments as provided by the user.
3. **inputs**: A list of characteristics of the clustering process.
4. **algorithm**: A list of all objects associated with the clustering procedure, such as original cluster objects (only if `algorithm_in_output = TRUE`).
5. **clusters**: A data.frame containing the clustering results.

If `algorithm_in_output = TRUE`, the algorithm slot includes the output of [fastclara](#).

nhclu_clarans

Non-hierarchical clustering: CLARANS

Description

This function performs non-hierarchical clustering based on dissimilarity using partitioning around medoids, implemented via the Clustering Large Applications based on RANdomized Search (CLARANS) algorithm.

Usage

```
nhclu_clarans(
  dissimilarity,
  index = names(dissimilarity)[3],
  seed = NULL,
  n_clust = c(1, 2, 3),
  numlocal = 2,
  maxneighbor = 0.025,
  algorithm_in_output = TRUE
)
```

Arguments

dissimilarity	The output object from dissimilarity() or similarity_to_dissimilarity() , or a dist object. If a data.frame is used, the first two columns should represent pairs of sites (or any pair of nodes), and the subsequent column(s) should contain the dissimilarity indices.
index	The name or number of the dissimilarity column to use. By default, the third column name of dissimilarity is used.

seed	A value for the random number generator (NULL for random initialization by default).
n_clust	An integer vector or a single integer specifying the desired number(s) of clusters.
numlocal	An integer defining the number of local searches to perform.
maxneighbor	A positive numeric value defining the maximum number of neighbors to consider for each local search.
algorithm_in_output	A boolean indicating whether the original output of fastclarans should be included in the output. Defaults to TRUE (see Value).

Details

Based on [fastkmedoids](#) package ([fastclarans](#)).

Value

A list of class `bioregion.clusters` with five components:

1. **name**: A character string containing the name of the algorithm.
2. **args**: A list of input arguments as provided by the user.
3. **inputs**: A list of characteristics of the clustering process.
4. **algorithm**: A list of all objects associated with the clustering procedure, such as original cluster objects (only if `algorithm_in_output = TRUE`).
5. **clusters**: A data.frame containing the clustering results.

If `algorithm_in_output = TRUE`, the algorithm slot includes the output of [fastclarans](#).

#clust <- nhclu_clarans(dissim, index = "Simpson", n_clust = 5)
```

 nhclu_dbscan

Non-hierarchical clustering: DBSCAN

Description

This function performs non-hierarchical clustering based on dissimilarity using the Density-Based Spatial Clustering of Applications with Noise (DBSCAN) algorithm.

Usage

```
nhclu_dbscan(
  dissimilarity,
  index = names(dissimilarity)[3],
  minPts = NULL,
  eps = NULL,
  plot = TRUE,
  algorithm_in_output = TRUE,
  ...
)
```

Arguments

- | | |
|---------------|---|
| dissimilarity | The output object from dissimilarity() or similarity_to_dissimilarity() , or a dist object. If a data.frame is used, the first two columns should represent pairs of sites (or any pair of nodes), and the subsequent column(s) should contain the dissimilarity indices. |
| index | The name or number of the dissimilarity column to use. By default, the third column name of dissimilarity is used. |
| minPts | A numeric vector or a single numeric value specifying the minPts argument of dbscan::dbscan() . minPts is the minimum number of points to form a dense region. By default, it is set to the natural logarithm of the number of sites in dissimilarity. See Details for guidance on choosing this parameter. |
| eps | A numeric vector or a single numeric value specifying the eps argument of dbscan::dbscan() . eps specifies how similar points should be to each other to be considered part of a cluster. See Details for guidance on choosing this parameter. |

plot	A boolean indicating whether the k-nearest neighbor distance plot should be displayed.
algorithm_in_output	A boolean indicating whether the original output of <code>dbscan::dbscan</code> should be included in the output. Defaults to TRUE (see Value).
...	Additional arguments to be passed to <code>dbscan()</code> (see <code>dbscan::dbscan</code>).

Details

The DBSCAN (Density-Based Spatial Clustering of Applications with Noise) algorithm clusters points based on the density of neighbors around each data point. It requires two main arguments: `minPts`, the minimum number of points to identify a core, and `eps`, the radius used to find neighbors.

Choosing `minPts`: This determines how many points are necessary to form a cluster. For example, what is the minimum number of sites expected in a bioregion? Choose a value sufficiently large for your dataset and expectations.

Choosing `eps`: This determines how similar sites should be to form a cluster. If `eps` is too small, most points will be considered too distinct and marked as noise. If `eps` is too large, clusters may merge. The value of `eps` depends on `minPts`. It is recommended to choose `eps` by identifying a knee in the k-nearest neighbor distance plot.

By default, the function attempts to find a knee in this curve automatically, but the result is uncertain. Users should inspect the graph and modify `eps` accordingly. To explore `eps` values, run the function initially without defining `eps`, review the recommendations, and adjust as needed based on clustering results.

Value

A list of class `bioregion.clusters` with five components:

1. **name:** A character string containing the name of the algorithm.
2. **args:** A list of input arguments as provided by the user.
3. **inputs:** A list of characteristics of the clustering process.
4. **algorithm:** A list of all objects associated with the clustering procedure, such as original cluster objects (only if `algorithm_in_output = TRUE`).
5. **clusters:** A `data.frame` containing the clustering results.

If `algorithm_in_output = TRUE`, the `algorithm` slot includes the output of `dbscan::dbscan`.

colnames(comat) <- paste0("Species",1:25)

dissim <- dissimilarity(comat, metric = "all")

clust1 <- nhclu_dbscan(dissim, index = "Simpson")
clust2 <- nhclu_dbscan(dissim, index = "Simpson", eps = 0.2)
clust3 <- nhclu_dbscan(dissim, index = "Simpson", minPts = c(5, 10, 15, 20),
  eps = c(.1, .15, .2, .25, .3))
```

 nhclu_kmeans

Non-hierarchical clustering: K-means analysis

Description

This function performs non-hierarchical clustering based on dissimilarity using a k-means analysis.

Usage

```
nhclu_kmeans(
  dissimilarity,
  index = names(dissimilarity)[3],
  seed = NULL,
  n_clust = c(1, 2, 3),
  iter_max = 10,
  nstart = 10,
  algorithm = "Hartigan-Wong",
  algorithm_in_output = TRUE
)
```

Arguments

dissimilarity	The output object from dissimilarity() or similarity_to_dissimilarity() , or a dist object. If a data.frame is used, the first two columns should represent pairs of sites (or any pair of nodes), and the subsequent column(s) should contain the dissimilarity indices.
index	The name or number of the dissimilarity column to use. By default, the third column name of dissimilarity is used.

seed	A value for the random number generator (NULL for random by default).
n_clust	An integer vector or a single integer value specifying the requested number(s) of clusters.
iter_max	An integer specifying the maximum number of iterations for the k-means method (see kmeans).
nstart	An integer specifying how many random sets of n_clust should be selected as starting points for the k-means analysis (see kmeans).
algorithm	A character specifying the algorithm to use for k-means (see kmeans). Available options are Hartigan-Wong, Lloyd, Forgy, and MacQueen.
algorithm_in_output	A boolean indicating whether the original output of kmeans should be included in the output. Defaults to TRUE (see Value).

Details

This method partitions data into k groups such that the sum of squares of Euclidean distances from points to the assigned cluster centers is minimized. K-means cannot be applied directly to dissimilarity or beta-diversity metrics because these distances are not Euclidean. Therefore, it first requires transforming the dissimilarity matrix using Principal Coordinate Analysis (PCoA) with [pcoa](#), and then applying k-means to the coordinates of points in the PCoA.

Because this additional transformation alters the initial dissimilarity matrix, the partitioning around medoids method ([nhclu_pam](#)) is preferred.

Value

A list of class `bioregion.clusters` with five components:

1. **name**: A character string containing the name of the algorithm.
2. **args**: A list of input arguments as provided by the user.
3. **inputs**: A list of characteristics of the clustering process.
4. **algorithm**: A list of all objects associated with the clustering procedure, such as original cluster objects (only if `algorithm_in_output = TRUE`).
5. **clusters**: A data.frame containing the clustering results.

If `algorithm_in_output = TRUE`, the `algorithm` slot includes the output of [kmeans](#).

dissim <- dissimilarity(comat, metric = "all")

clust <- nhclu_kmeans(dissim, n_clust = 2:10, index = "Simpson")
```

 nhclu_pam

Non-hierarchical clustering: Partitioning Around Medoids

Description

This function performs non-hierarchical clustering based on dissimilarity using partitioning around medoids (PAM).

Usage

```
nhclu_pam(
  dissimilarity,
  index = names(dissimilarity)[3],
  seed = NULL,
  n_clust = c(1, 2, 3),
  variant = "faster",
  nstart = 1,
  cluster_only = FALSE,
  algorithm_in_output = TRUE,
  ...
)
```

Arguments

dissimilarity	The output object from dissimilarity() or similarity_to_dissimilarity() , or a dist object. If a data.frame is used, the first two columns should represent pairs of sites (or any pair of nodes), and the subsequent column(s) should contain the dissimilarity indices.
index	The name or number of the dissimilarity column to use. By default, the third column name of dissimilarity is used.
seed	A value for the random number generator (NULL for random by default).
n_clust	An integer vector or a single integer value specifying the requested number(s) of clusters.

variant	A character string specifying the PAM variant to use. Defaults to faster. Available options are original, o_1, o_2, f_3, f_4, f_5, or faster. See pam for more details.
nstart	An integer specifying the number of random starts for the PAM algorithm. Defaults to 1 (for the faster variant).
cluster_only	A boolean specifying whether only the clustering results should be returned from the pam function. Setting this to TRUE makes the function more efficient.
algorithm_in_output	A boolean indicating whether the original output of pam should be included in the result. Defaults to TRUE (see Value).
...	Additional arguments to pass to pam() (see pam).

Details

This method partitions the data into the chosen number of clusters based on the input dissimilarity matrix. It is more robust than k-means because it minimizes the sum of dissimilarities between cluster centers (medoids) and points assigned to the cluster. In contrast, k-means minimizes the sum of squared Euclidean distances, which makes it unsuitable for dissimilarity matrices that are not based on Euclidean distances.

Value

A list of class `bioregion.clusters` with five components:

1. **name:** A character string containing the name of the algorithm.
2. **args:** A list of input arguments as provided by the user.
3. **inputs:** A list of characteristics of the clustering process.
4. **algorithm:** A list of all objects associated with the clustering procedure, such as original cluster objects (only if `algorithm_in_output = TRUE`).
5. **clusters:** A data.frame containing the clustering results.

If `algorithm_in_output = TRUE`, the `algorithm` slot includes the output of [pam](#).

similarity	<i>Compute similarity metrics between sites based on species composition</i>
------------	--

Description

This function generates a data.frame where each row provides one or several similarity metrics between pairs of sites, based on a co-occurrence matrix with sites as rows and species as columns.

Usage

```
similarity(comat, metric = "Simpson", formula = NULL, method = "prodmatrix")
```

Arguments

comat	A co-occurrence matrix with sites as rows and species as columns.
metric	A character vector or a single character string specifying the metrics to compute (see Details). Available options are "abc", "ABC", "Jaccard", "Jaccardturn", "Sorensen", "Simpson", "Bray", "Brayturn", and "Euclidean". If "all" is specified, all metrics will be calculated. Can be set to NULL if formula is used.
formula	A character vector or a single character string specifying custom formula(s) based on the a, b, c, A, B, and C quantities (see Details). The default is NULL.
method	A character string specifying the method to compute abc (see Details). The default is "prodmatrix", which is more efficient but memory-intensive. Alternatively, "loops" is less memory-intensive but slower.

Details

With a the number of species shared by a pair of sites, b species only present in the first site and c species only present in the second site.

$$\text{Jaccard} = 1 - (b + c) / (a + b + c)$$

$$\text{Jaccardturn} = 1 - 2\min(b, c) / (a + 2\min(b, c)) \text{ (Baselga, 2012)}$$

$$\text{Sorensen} = 1 - (b + c) / (2a + b + c)$$

$$\text{Simpson} = 1 - \min(b, c) / (a + \min(b, c))$$

If abundances data are available, Bray-Curtis and its turnover component can also be computed with the following equation:

$$\text{Bray} = 1 - (B + C) / (2A + B + C)$$

$$\text{Brayturn} = 1 - \min(B, C) / (A + \min(B, C)) \text{ (Baselga, 2013)}$$

with A the sum of the lesser values for common species shared by a pair of sites. B and C are the total number of specimens counted at both sites minus A.

formula can be used to compute customized metrics with the terms a, b, c, A, B, and C. For example `formula = c("1 - pmin(b,c) / (a + pmin(b,c))", "1 - (B + C) / (2*A + B + C)")` will compute the Simpson and Bray-Curtis similarity metrics, respectively. Note that `pmin` is used in the Simpson formula because a, b, c, A, B and C are numeric vectors.

Euclidean computes the Euclidean similarity between each pair of site following this equation:

$$\text{Euclidean} = 1 / (1 + d_{ij})$$

Where `dij` is the Euclidean distance between site i and site j in terms of species composition.

Value

A `data.frame` with the additional class `bioregion.pairwise.metric`, containing one or several similarity metrics between pairs of sites. The first two columns represent the pairs of sites. There is one column per similarity metric provided in `metric` and `formula`, except for the `abc` and `ABC` metrics, which are stored in three separate columns (one for each letter).

Associated functions: [dissimilarity](#) [similarity_to_dissimilarity](#)

Examples

```
comat <- matrix(sample(0:1000, size = 50, replace = TRUE,
prob = 1 / 1:1001), 5, 10)
rownames(comat) <- paste0("Site", 1:5)
colnames(comat) <- paste0("Species", 1:10)
```

```
sim <- similarity(comat, metric = c("abc", "ABC", "Simpson", "Brayturn"))

sim <- similarity(comat, metric = "all",
formula = "1 - (b + c) / (a + b + c)")
```

similarity_to_dissimilarity

Convert similarity metrics to dissimilarity metrics

Description

This function converts a data.frame of similarity metrics between sites into dissimilarity metrics (beta diversity).

Usage

```
similarity_to_dissimilarity(similarity, include_formula = TRUE)
```

Arguments

similarity The output object from [similarity\(\)](#) or [dissimilarity_to_similarity\(\)](#).
include_formula A boolean indicating whether metrics based on custom formula(s) should also be converted (see Details). The default is TRUE.

Value

A data.frame with additional class `bioregion.pairwise.metric`, providing dissimilarity metric(s) between each pair of sites based on a similarity object.

Note

The behavior of this function changes depending on column names. Columns `Site1` and `Site2` are copied identically. If there are columns called `a`, `b`, `c`, `A`, `B`, `C` they will also be copied identically. If there are columns based on your own formula (argument `formula` in [similarity\(\)](#)) or not in the original list of similarity metrics (argument `metrics` in [similarity\(\)](#)) and if the argument `include_formula` is set to `FALSE`, they will also be copied identically. Otherwise there are going to be converted like they other columns (default behavior).

If a column is called `Euclidean`, its distance will be calculated based on the following formula:

Euclidean distance = $(1 - \text{Euclidean similarity}) / \text{Euclidean similarity}$

Otherwise, all other columns will be transformed into dissimilarity with the following formula:

dissimilarity = $1 - \text{similarity}$

```

site_species_metrics *Calculate contribution metrics of sites and species*

Description

This function calculates metrics to assess the contribution of a given species or site to its bioregion.

Usage

```
site_species_metrics(  
  bioregionalization,  
  comat,  
  indices = c("rho"),  
  net = NULL,  
  site_col = 1,  
  species_col = 2  
)
```

Arguments

bioregionalization	A <code>bioregion.clusters</code> object.
comat	A co-occurrence matrix with sites as rows and species as columns.
indices	A character specifying the contribution metric to compute. Available options are <code>rho</code> , <code>affinity</code> , <code>fidelity</code> , <code>indicator_value</code> and <code>Cz</code> .
net	NULL by default. Required for <code>Cz</code> indices. A <code>data.frame</code> where each row represents an interaction between two nodes and an optional third column indicating the interaction's weight.
site_col	A number indicating the position of the column containing the sites in <code>net</code> . 1 by default.
species_col	A number indicating the position of the column containing the species in <code>net</code> . 2 by default.

Details

The ρ metric is derived from Lenormand et al. (2019) with the following formula:

$$\rho_{ij} = \frac{n_{ij} - \frac{n_i n_j}{n}}{\sqrt{\left(\frac{n - n_j}{n - 1}\right) \left(1 - \frac{n_j}{n}\right) \frac{n_i n_j}{n}}}$$

where n is the number of sites, n_i is the number of sites in which species i is present, n_j is the number of sites in bioregion j , and n_{ij} is the number of occurrences of species i in sites of bioregion j .

Affinity A , fidelity F , and individual contributions $IndVal$ describe how species are linked to their bioregions. These metrics are described in Bernardo-Madrid et al. (2019):

- Affinity of species to their region: $A_i = \frac{R_i}{Z}$, where R_i is the occurrence/range size of species i in its associated bioregion, and Z is the total size (number of sites) of the bioregion. High affinity indicates that the species occupies most sites in its bioregion.
- Fidelity of species to their region: $F_i = \frac{R_i}{D_i}$, where R_i is the occurrence/range size of species i in its bioregion, and D_i is its total range size. High fidelity indicates that the species is not present in other regions.
- Indicator Value of species: $IndVal = F_i \cdot A_i$.

`Cz` metrics are derived from Guimerà & Amaral (2005):

- Participation coefficient: $C_i = 1 - \sum_{s=1}^{N_M} \left(\frac{k_{is}}{k_i}\right)^2$, where k_{is} is the number of links of node i to nodes in bioregion s , and k_i is the total degree of node i . A high value means links are uniformly distributed; a low value means links are within the node's bioregion.
- Within-bioregion degree z-score: $z_i = \frac{k_i - \overline{k_{si}}}{\sigma_{k_{si}}}$, where k_i is the number of links of node i to nodes in its bioregion s_i , $\overline{k_{si}}$ is the average degree of nodes in s_i , and $\sigma_{k_{si}}$ is the standard deviation of degrees in s_i .

Value

A `data.frame` with columns `Bioregion`, `Species`, and the desired summary statistics, or a list of `data.frames` if `Cz` and other indices are selected.

site_species_subset	<i>Extract a subset of sites or species from a bioregion.clusters object</i>
---------------------	--

Description

This function extracts a subset of nodes based on their type ("site" or "species") from a `bioregion.clusters` object, which contains both types of nodes (sites and species).

Usage

```
site_species_subset(clusters, node_type = "site")
```

Arguments

<code>clusters</code>	An object of class <code>bioregion.clusters</code> .
<code>node_type</code>	A character string indicating the type of nodes to extract. Possible values are "site" or "species". The default is "site".

Value

An object of class `bioregion.clusters` containing only the specified node type (sites or species).

Note

Network clustering functions (prefixed with `netclu_`) may return both types of nodes (sites and species) when applied to bipartite networks (using the `bipartite` argument). In such cases, the type of nodes included in the output can be specified with the `return_node_type` argument. This function allows you to extract a particular type of nodes (sites or species) from the output and adjust the `return_node_type` attribute accordingly.

vegedf*Spatial distribution of Mediterranean vegetation (data.frame)*

Description

A dataset containing the abundance of 3,697 species in 715 sites.

Usage

vegedf

Format

A data.frame with 460,878 rows and 3 columns:

Site Unique site identifier (corresponding to the field ID of vegesp)

Species Unique species identifier

Abundance Species abundance

Source

[doi:10.1002/ece3.4718](https://doi.org/10.1002/ece3.4718)

vegemat*Spatial distribution of Mediterranean vegetation (co-occurrence matrix)*

Description

A dataset containing the abundance of each of the 3,697 species in each of the 715 sites.

Usage

vegemat

Format

A co-occurrence matrix with sites as rows and species as columns. Each element of the matrix represents the abundance of the species in the site.

vegesf	<i>Spatial distribution of Mediterranean vegetation (spatial grid)</i>
--------	--

Description

A dataset containing the geometry of the 715 sites.

Usage

vegesf

Format

A

ID Unique site identifier

geometry Geometry of the site
